## SUMMARY

Dorsal root ganglion (DRG) sensory neuron subtypes defined by their *in vivo* properties display distinct intrinsic electrical properties. We used bulk RNA sequencing of genetically labeled neurons and electrophysiological analyses to define ion channel contributions to the intrinsic electrical properties of DRG neuron subtypes. The transcriptome profiles of eight DRG neuron subtypes revealed differentially expressed and functionally relevant genes, including voltage-gated ion channels. Guided by these data, electrophysiological analyses using pharmacological and genetic manipulations as well as computational modeling of DRG neuron subtypes were undertaken to assess the functions of select voltage-gated potassium channels (Kv1, Kv2, Kv3, and Kv4) in shaping action potential (AP) waveforms and firing patterns. Our findings show that the transcriptome profiles have predictive value for defining ion channel contributions to sensory neuron subtype-specific intrinsic physiological properties. The distinct ensembles of voltage-gated ion channels predicted to underlie the unique intrinsic physiological properties of eight DRG neuron subtypes are presented.

## INTRODUCTION

Dorsal root ganglia (DRG) neurons are the first-order neurons in the somatosensory afferent pathway, transducing physical, thermal, and chemical stimuli acting in the periphery into electrical signals and conveying these signals to the CNS for action and perception. DRG neurons are pseudo-unipolar, with one axonal

branch that innervates peripheral tissues, including the skin, and another that projects to the spinal cord and, in some cases, the dorsal column nuclei of the brainstem (Abraira and Ginty, 2013). Decades of research has shown that DRG sensory neurons exhibit a wide range of peripheral ending morphologies, central projection patterns, and physiological properties and that they are tuned to distinct modalities or features of sensory stimuli. DRG neurons are thus classified into distinct subtypes (Abraira and Ginty, 2013; Basbaum et al., 2009; Delmas et al., 2011; Willis and Coggeshall, 2004; Woolf and Ma, 2007; Zimmerman et al., 2014).

How do DRG neuron subtypes transduce sensory stimuli into patterns of action potentials (APs) that propagate to the CNS? Stimuli impinging on the skin and other organs activate transduction receptors or ion channels on peripheral terminals of DRG sensory neurons, resulting in the generation of receptor potentials. Transduction channels include thermosensitive and mechanosensitive cation channels, such as TrpV1, TrpM8, and Piezo2 (Julius, 2013; Ranade et al., 2015). Receptor potentials generated at axon terminals may be integrated over space and time and subject to modulation by locally expressed voltage-gated ion channels (Bai et al., 2015; François et al., 2015; Grigg, 1986; Heidenreich et al., 2011; Wang and Lewin, 2011). Suprathreshold receptor potentials trigger activation of voltage-gated ion channels at initiation sites to generate APs that propagate along the length of the axon, into its central axonal branches and terminals. Although the transduction machinery determines the general stimulus modality to which DRG sensory neurons respond, voltage-gated ion channels modulate generator currents and control AP thresholds, AP firing patterns, propagation, and synaptic transmission (Du et al., 2014; Heidenreich et al., 2011; Muqeem et al., 2018; Sundt et al., 2015; Tsantoulas and McMahon, 2014; Waxman and Zamponi, 2014) and are therefore determinants of DRG sensory neuron function.

It has long been established that a wide range of voltage-gated sodium (Nav), calcium (Cav), and potassium (Kv) channels are

expressed in DRG neurons, and several of these ion channels are now appreciated as targets for developing drugs to treat pain (Dib-Hajj et al., 2010; Tsantoulas and McMahon, 2014; Waxman and Zamponi, 2014). Most electrophysiological studies have focused on small-diameter DRG neurons, most (but not all) of which correspond to unmyelinated nociceptors, with some studies distinguishing subpopulations of small-diameter neurons based on lectin binding or capsaicin sensitivity (Du and Gamper, 2013; Petruska et al., 2000; Rau et al., 2014; Vydyananthan et al., 2005). Much less is known about the complement of ion channels in physiologically defined DRG neuron subtypes (for example, mechanoreceptors) or how they relate to the firing behaviors in these subtypes, especially medium- and large-diameter DRG neurons, which comprise a highly heterogeneous population. Therefore, a major current challenge is determining how intrinsic electrical properties of the diverse, physiologically distinct mammalian somatosensory neuron subtypes are specified.

Recent advances in the development of mouse genetic tools to interrogate the major classes of DRG sensory neurons afford an opportunity to investigate the relationship between patterns of voltage-gated ion channel expression and the intrinsic physiological properties of DRG neuron subtypes. Genetic tools now exist for labeling five principal low-threshold mechanoreceptor subtypes (LTMRs) (i.e., touch receptors) that innervate hairy skin: these are the C-LTMRs, A $\delta$ -LTMRs, A $\beta$  RA-LTMRs, A $\beta$  SA1-LTMRs, and A $\beta$  field-LTMRs (Zimmerman et al., 2014; Bai et al., 2015). Here, we used genetic tools to identify intrinsic molecular determinants of the physiological properties of LTMR subtypes and, for comparison, nociceptor subtypes and proprioceptors (Hippenmeyer et al., 2005; Zylka et al., 2005). We employed genetic labeling to purify these DRG neuron subtypes and performed deep RNA sequencing to identify candidate genes that underlie their subtype-specific intrinsic electrophysiological properties. Our analysis revealed many genes, including voltage-gated ion channels, that are differentially expressed across the five LTMR subtypes, peptidergic and polymodal non-peptidergic nociceptors, and proprioceptors. Guided by these gene expression profiles, we performed electrophysiological experiments and computational modeling to define contributions of differentially expressed Kv channels to sensory neuron subtype-specific intrinsic electrical properties. Our findings reveal the distinct voltage-gated ion channel constellations that support unique intrinsic properties of the major DRG sensory neuron classes.

## RESULTS

### Somatosensory Neurons Exhibit Subtype-Specific Intrinsic Membrane Properties and Mechanosensitivity

The availability of mouse genetic tools for selective labeling of functionally defined sensory neuron subtypes *in vivo* enables a comprehensive analysis of subtype-specific intrinsic physiological properties of these subtypes. We focused on eight major classes of DRG sensory neurons labeled *in vivo* using genetically modified mice. These are the MrgD $^+$  polymodal nonpeptidergic nociceptors, the broad class of CGRP $^+$  (peptidergic) nociceptors, five functionally defined LTMR subtypes (C-LTMRs, A $\delta$ –

LTMRs, A $\beta$  RA-LTMRs, A $\beta$  SA1-LTMRs, and A $\beta$  field-LTMRs), and proprioceptors. The genetic tools used to label each of these neuronal populations are *MrgD*<sup>EGFP</sup> mice to label MrgD $^+$  non-peptidergic nociceptors (Zylka et al., 2005), *Calca(CGRP)*-EGFP BAC transgenic mice for peptidergic nociceptors (Bai et al., 2015), *Th*<sup>2A-CreER</sup>; *R26*<sup>lsl-tdTomato</sup> (*Ai14*) mice (tamoxifen 2 mg/day at postnatal day 13 [P13] to P14) for C-LTMRs (Abraira et al., 2017), *TrkB*<sup>CreER</sup>; *Ai14* mice (tamoxifen 2 mg/day at embryonic day 12.5 [E12.5] to E13.5) for A $\delta$ -LTMRs (Rutlin et al., 2014), *Npy2r-GFP* BAC transgenic mice for A $\beta$  RA-LTMRs (Li et al., 2011), *TrkC*<sup>CreER</sup>; *Ret*<sup>EGFP</sup> mice (tamoxifen 3 mg at E12.5) for A $\beta$  SA1-LTMRs (Bai et al., 2015; Jain et al., 2006), *TrkC*<sup>CreER</sup>; *Ret*<sup>EGFP</sup> mice (tamoxifen 2 mg/day at P13 to P14) for A $\beta$  field-LTMRs (Bai et al., 2015), and *Pv*<sup>RES-Cre</sup>; *Ai14* mice to label proprioceptors (Hippenmeyer et al., 2005; Figure 2A). We estimate that these eight populations account for ~85% of all DRG neurons (Bai et al., 2015; Gorokhova et al., 2014; Li et al., 2011; Lu et al., 2017).

### Firing Patterns and AP Waveforms

To define the intrinsic electrical properties of DRG neuron subtypes, neurons from each of the genetically labeled mouse lines were acutely dissociated and used for whole-cell patch-clamp recordings. The neuron subtypes displayed distinct electrophysiological signatures. MrgD $^+$  nonpeptidergic nociceptors and C-LTMRs both showed repetitive low-frequency firing in response to current injection, reaching maximum frequencies of ~12 Hz and ~26 Hz, respectively (Figures 1A, 1B, and 1H). C-LTMRs exhibited a distinctive delayed firing pattern with a long latency to the first AP followed by regular repetitive spiking (Figure 1B). A $\delta$ -LTMRs showed strong adaptation, firing 5 or 6 spikes in the first few hundred milliseconds and then becoming silent (Figures 1C and 1H). A $\beta$  RA-LTMRs and proprioceptors both fired repetitively over a wide range of frequencies, with the frequency increasing with current amplitude to a maximum of ~180 and ~220 Hz, respectively (Figures 1D, 1G, and 1H). Both A $\beta$  field-LTMRs and A $\beta$  SA1-LTMRs typically displayed very strong adaptation, firing only in the first 50 ms of current injection (Figures 1E, 1F, and 1H). Strikingly, A $\beta$  SA1-LTMRs fired no more than two spikes, regardless of the current intensity used for stimulation.

The finding that A $\beta$  SA1-LTMRs fire non-repetitively in response to sustained current injection *in vitro* is counterintuitive because these neurons fire repetitively and adapt slowly to sustained skin indentation *in vivo* (Wellnitz et al., 2010; Zimmerman et al., 2014). We therefore asked whether A $\beta$  SA1-LTMRs could fire repetitively *in vitro* by applying a train of short current pulses (250  $\mu$ s). Indeed, all A $\beta$  SA1-LTMRs faithfully followed pulse stimulation up to ~300 Hz (Figure 1E). *In vivo*, A $\beta$  SA1-LTMR cutaneous endings are associated with Merkel cells, which are themselves mechanosensitive and transmit excitatory signals to A $\beta$  SA1-LTMRs (Chang et al., 2016; Ikeda et al., 2014; Maksimovic et al., 2013, 2014; Woo et al., 2014). These *in vitro* results are thus consistent with the notion that the repetitive firing of A $\beta$  SA1-LTMRs in response to static indentation *in vivo* depends on their association with Merkel cells. Proprioceptors could follow repetitive stimulation at even higher frequencies (400–600 Hz) than A $\beta$  SA1-LTMRs, and maximal firing frequencies of both were far higher than that achieved by C-LTMRs (30–100 Hz).

(legend on next page)

The DRG neuron subtypes also display different AP waveforms. MrgD<sup>+</sup> nonpeptidergic nociceptors and C-LTMRs have much wider APs (widths ~2 ms at half spike height) than other LTMR subtypes and proprioceptors, with AP widths <0.5 ms (Figures 1B and 1D). The broad APs seen in MrgD<sup>+</sup> nonpeptidergic nociceptors and C-LTMRs agree with previous results showing broad APs in cell bodies associated with unmyelinated C-fibers in rats (Harper and Lawson, 1985). Broad APs may facilitate AP propagation in small unmyelinated axons with short-length constants, which are susceptible to spike failure, especially at the T-junction within the dorsal root ganglion (Gemes et al., 2013; Sundt et al., 2015).

Our electrophysiological analyses of MrgD<sup>+</sup> nonpeptidergic nociceptors, the five LTMR subtypes, and proprioceptors indicate that these populations are largely homogeneous in terms of within-group firing patterns and AP waveforms. On the other hand, the CGRP<sup>+</sup> peptidergic nociceptors displayed a range of firing patterns and AP waveforms (Figure S1), consistent with the idea that CGRP labels a large, functionally and morphologically heterogeneous group of neurons that can be further subdivided based on their intrinsic physiological properties (Arcourt et al., 2017; Bardoni et al., 2014; Han et al., 2013; Patil et al., 2018).

#### Mechanically Activated Currents

To assess intrinsic mechanosensitivity of the major DRG sensory neuron subtypes, genetically labeled DRG neurons were used for *in vitro* whole-cell mechanoclamp experiments in which a controlled mechanical stimulus was applied to the cell body using a piezo-driven glass probe and resulting currents were recorded (Hao and Delmas, 2011; McCarter et al., 1999). All labeled neuronal types were used for this analysis, except for CGRP<sup>+</sup> peptidergic nociceptors, which were excluded because of their heterogeneous firing properties (Figure S1). With a series of 500-ms mechanical stimulations of increasing displacement, all five LTMR subtypes and proprioceptors displayed obvious

mechanically activated inward currents ( $I_{\text{mechs}}$ ) (Figures 1M–1S), and most MrgD<sup>+</sup> nonpeptidergic nociceptors displayed minimal  $I_{\text{mechs}}$  indistinguishable from noise (100 pA; Figures 1L and 1S).  $I_{\text{mech}}$  in DRG neuron subtypes also displayed different decay kinetics.  $I_{\text{mech}}$ s of A $\delta$ -LTMRs, A $\beta$ -LTMRs, and proprioceptors have fast relaxation kinetics with a time constant mostly shorter than 30 ms (Figure 1T). In comparison,  $I_{\text{mech}}$  of C-LTMRs decays slower with an average time constant around 100 ms.

Taken together, these *in vitro* electrophysiological recordings indicate that most functionally distinct DRG neuron subtypes are distinguished by unique combinations of firing patterns, AP waveforms, and mechanical sensitivities; A $\beta$  field-LTMRs and A $\beta$  SA1-LTMRs displayed similar intrinsic properties despite major differences in their *in vivo* responses to mechanical stimuli acting on the skin, likely reflecting their unique peripheral terminal morphologies and the skin cell types with which they associate (Zimmerman et al., 2014; Bai et al., 2015). Differences in intrinsic physiological properties among the subtypes are likely due to differences in ion channels and components of the mechanotransduction machinery that they express.

#### Deep RNA Sequencing to Generate Transcriptome Profiles of Major DRG Neuron Subtypes

To explore the molecular basis of the distinct intrinsic membrane properties and other distinguishing features of DRG neuron subtypes, we undertook an RNA sequencing approach to generate transcriptome profiles for each of the eight major DRG neuron subtypes. We made use of the aforementioned genetic tools that selectively label each of these subtypes with fluorescent reporters, first purifying labeled neurons to homogeneity using flow cytometry (fluorescence-activated cell sorting [FACS]) and then extracting RNA from these purified neuronal populations (Figures 2A and 2B). DRGs from all axial levels were used for FACS, except for proprioceptors, which were purified from thoracic ganglia, because the  $PV^{RES-Cre}$ ; *Ai14* proprioceptor

#### Figure 1. Distinct Intrinsic Physiological Properties and Mechanosensitivity of Eight Major DRG Sensory Neuron Subtypes

- (A–G) Representative *in vitro* spiking patterns of MrgD<sup>+</sup> nonpeptidergic nociceptors (A), C-LTMRs (B), A $\delta$ -LTMRs (C), A $\beta$  RA-LTMRs (D), A $\beta$  SA1-LTMRs (E), A $\beta$  Field-LTMRs (F), and proprioceptors (G), during 500-ms injections of depolarizing current steps of increasing magnitude.
- (H) Number of APs during 500-ms current injections for each subtype (mean  $\pm$  SEM) plotted against current density, with expanded y axis shown in the bottom panel. N = 9 for MrgD<sup>+</sup> nonpeptidergic nociceptors; n = 28 for C-LTMRs; n = 19 for A $\delta$ -LTMRs; n = 25 for A $\beta$  RA-LTMRs; n = 11 for A $\beta$  SA1-LTMRs; n = 16 for A $\beta$  field-LTMRs; n = 14 for proprioceptors.
- (I) Representative AP waveforms of DRG neuron subtype (first AP evoked by 500-ms current injection at or near threshold).
- (J) AP widths (measured at half-maximal spike amplitude) of DRG neuron subtypes (mean  $\pm$  SEM; n's as in H). One-way ANOVA with Tukey's multiple comparisons test showed that MrgD<sup>+</sup> nonpeptidergic nociceptors and C-LTMRs are different from each other ( $p = 0.036$ ) and from all other subtypes ( $p < 0.001$ ).
- (K) Survival plot depicting the percentages of C-LTMRs (n = 8), A $\beta$  SA1-LTMRs (n = 5), and proprioceptors (n = 9) whose repetitive firing successfully followed 250- $\mu$ s pulse stimulation at the indicated frequencies.
- (L–R) Representative traces of  $I_{\text{mech}}$  during 500-ms step displacements of increasing magnitudes for each DRG neuron subtype: MrgD<sup>+</sup> nonpeptidergic nociceptors (L), C-LTMRs (M), A $\delta$ -LTMRs (N), A $\beta$  RA-LTMRs (O), A $\beta$  SA1-LTMRs (P), A $\beta$  Field-LTMRs (Q), and proprioceptors (R).
- (S) Maximal amplitudes of  $I_{\text{mech}}$  for each DRG neuron subtypes (mean  $\pm$  SEM). The maximal amplitudes of  $I_{\text{mech}}$  are significantly different ( $p < 0.0001$ ). In particular, maximal amplitudes of  $I_{\text{mech}}$  measured in MrgD<sup>+</sup> nonpeptidergic nociceptors are significantly smaller than those measured in A $\beta$  RA-LTMRs ( $p = 0.0072$ ), A $\beta$  SA1-LTMRs ( $p = 0.0014$ ), and A $\beta$  field-LTMRs ( $p < 0.0001$ ) and proprioceptors ( $p = 0.0345$ ) (Kruskal-Wallis test with multiple comparisons of every subtype against MrgD<sup>+</sup> nonpeptidergic nociceptors).  $I_{\text{mech}}$  measured in MrgD<sup>+</sup> nonpeptidergic nociceptors is not significantly different from 100 pA, which is the noise level ( $p = 0.4450$ ), and  $I_{\text{mech}}$ s measured in five LTMRs and proprioceptors are ( $p < 0.01$ ) (One-sample t test). n = 7 for MrgD<sup>+</sup> nonpeptidergic nociceptors; n = 16 for C-LTMRs; n = 12 for A $\delta$ -LTMRs; n = 15 for A $\beta$  RA-LTMRs; n = 8 for A $\beta$  SA1-LTMRs; n = 15 for A $\beta$  field-LTMRs; and n = 14 for proprioceptors.
- (T) Time constant ( $\tau$ ) of  $I_{\text{mech}}$  relaxation kinetics for each DRG neuron subtype. Group mean and SEM are shown using error bars.  $\tau$ s of  $I_{\text{mech}}$  are significantly different among subtypes ( $p < 0.0001$ ). In particular,  $\tau$ s in C-LTMRs are significantly larger than those in A $\delta$ -LTMRs ( $p < 0.0001$ ), A $\beta$  RA-LTMRs ( $p = 0.0006$ ), and A $\beta$  field-LTMRs ( $p < 0.0001$ ) (Kruskal Wallis test with Dunn's multiple comparisons test), suggesting  $I_{\text{mech}}$  in C-LTMRs decays slower. n = 12 for C-LTMRs; n = 11 for A $\delta$ -LTMRs; n = 13 for A $\beta$  RA-LTMRs; n = 8 for A $\beta$  SA1-LTMRs; n = 15 for A $\beta$  field-LTMRs; and n = 11 for proprioceptors.

See also Figure S1.

*(legend on next page)*

labeling strategy was found to label a subset of limb level cutaneous LTMRs as well. DRGs from multiple mice were combined for FACS, and neurons from multiple rounds of sorting were combined to obtain sufficient amounts of RNA for each sequencing reaction. At least three biological replicates were sequenced for each neuronal subtype (Figure 2B). RNA libraries were prepared and subsequently sequenced using an Illumina HiSeq2000 platform at an average depth of ~70 million mapped reads per sample. This depth translates to an average detection level of 12,226 genes per sample. By using well-characterized mouse lines for specific labeling of neuronal subtypes, this analysis links gene expression patterns to sensory neuron subtypes defined by their distinct *in vivo* properties as well as their corresponding intrinsic properties, described above. This is particularly important for the three A $\beta$ -LTMR subtypes, which account for low percentages of DRG neurons and have not been previously resolved by single-cell sequencing approaches (Usoskin et al., 2015). Moreover, bulk RNA sequencing at the high depth afforded by our analysis approaches or reaches saturation of gene detection, including the detection of low-expressed genes, and facilitates identification of differentially expressed genes (DEGs) (Li et al., 2016). Using this deep sequencing strategy, we generated a matrix of read counts of all genes for each of the eight major DRG neuron subtypes.

The count matrix was transformed using a regularized logarithm (rlog) implemented in DESeq2 and thus rendered homoscedastic (Love et al., 2014). Unsupervised hierarchical clustering and principal-component analysis (PCA), using rlog values as measures of gene expression, showed that biological replicates for the same neuronal subtype cluster with each other (Figures 2C and S2A). This finding suggests that differences in gene expression across neuronal subtypes are not masked by variations across sequencing batches or noise introduced by experimental procedures.

We assessed the validity of the transcriptome profiles by examining expression patterns of several marker genes, including genes employed for the genetic tools and those whose expression patterns are well established in the DRG, as well as subtype-uniquely enriched genes (SUEGs) (Figures S2B and S2D; see STAR Methods for identification of SUEGs). For the former, expression patterns of several marker genes were found to be consistent with established knowledge (Figure S2B). For the latter, many SUEGs found in MrgD $^+$  nonpeptidergic nocicep-

tors, CGRP $^+$  peptidergic nociceptors, C-LTMRs, and proprioceptors are in agreement with prior single-cell sequencing studies that identified these subtypes (data not shown; Usoskin et al., 2015). Importantly, many SUEGs found in A $\beta$  RA-LTMRs, A $\beta$  SA1-LTMRs, and A $\beta$  field-LTMRs were identified here for the first time. Several SUEGs were also selected for validation by double immunostaining, double fluorescent *in situ* hybridization, and through characterization of a new mouse genetic tool (*Calb1*<sup>dgCre</sup>), which preferentially labels A $\beta$  RA-LTMRs (Figures 2D–2L and S2C–S2J). The deep transcriptome analysis of each of the eight major DRG neuron subtypes thus allows for the identification of gene candidates underlying subtype-specific properties, including intrinsic physiological properties.

### Functionally Relevant Genes Are Differentially Expressed across DRG Neuron Subtypes

In addition to differences in intrinsic physiological properties, DRG neuron subtypes differ in their developmental trajectories, peripheral terminal morphologies, response properties, central projection patterns and postsynaptic partners, and modes of presynaptic modulation of their central terminals (Abraira and Ginty, 2013; Dubin and Patapoutian, 2010; Fleming and Luo, 2013; Marmigère and Ernfors, 2007; Rudomin, 1999; Zimmerman et al., 2014, 2019). To determine gene expression patterns that may underlie these and other subtype-specific properties, we next examined the expression patterns of genes that fall within six functionally relevant categories implicated in shaping neuronal phenotype. The gene categories explored are transcription factors (TFs), cell adhesion molecules (CAMs), neuropeptides, synaptic exocytosis machinery, G-protein-coupled receptors (GPCRs), and ion channels (Chawla et al., 2013; Földy et al., 2016; Paul et al., 2017; Südhof, 2012). Among the top 75% of expressed genes ranked by average rlog values, there are 511 transcription factors, 306 cell adhesion molecules, 183 GPCRs, 175 ion channel genes, 94 synaptic vesicle exocytosis genes, and 23 neuropeptide genes. Genes from each of the categories are differentially expressed among the DRG neuron subtypes (Figures 3, S3A, and S3B; see STAR Methods for selection of genes for plotting). The most dramatic differences in gene expression patterns were often observed between small-diameter neuron subtypes (MrgD $^+$  nonpeptidergic nociceptors, CGRP $^+$  peptidergic nociceptors, and C-LTMRs) and medium and large-diameter subtypes (A $\delta$ -LTMRs, the three A $\beta$ -LTMR

**Figure 2. Transcriptome Profiling of Eight Major DRG Neuron Subtypes**

- (A) Genetic toolbox for labeling each of the eight DRG neuron subtypes.
- (B) Schematic of the RNA sequencing workflow.
- (C) Hierarchical clustering of samples based on the expression (represented in rlog transformed count values) of the top 1,000 genes that display the highest expression variance across samples using Euclidean distance.
- (D) Heatmap depicting expression patterns of SUEGs. Expression (represented in rlog transformed count values) differences compared to the average expression levels for each gene are plotted in the main heatmap. Average expression level of a gene was calculated by averaging expression across all samples and is plotted in a second heatmap next to the main heatmap. Only highly expressed genes (average expression levels in the upper 75<sup>th</sup> percentile) were selected for this analysis. Genes are ordered based on the subtype in which expression is enriched and their degree of enrichment. The top 5 most enriched genes for each of the neuronal subtypes are labeled. Genes whose expression were further tested with experiments as shown in (E)–(L) are labeled and marked with an asterisk.
- (E–L) Leftmost panels: dotplots depicting expression levels of selected genes across subtypes in rpkm (reads per kilobase per million reads) values. Three right panels: representative images of double immunostaining (E and H–J) or *in situ* hybridization (F, G, K, and L) of fluorescent reporters and select genes using DRG sections from genetically labeled mice. Sensory neuron subtype reporters and tested genes are shown in separate channels, and the degree of overlap between the two is shown in the merged images. n = 3 mice for (E)–(K); n = 2 mice for (L).

See STAR Methods for details.

(legend on next page)

subtypes, and proprioceptors), which is consistent with the expression structure revealed by hierarchical clustering and PCA analysis (Figures 2C and S2A). For example, most neuropeptide genes and several TRP channels, including TrpA, TrpM8, and TrpV1, are expressed at higher levels in the small-diameter neuron subtypes compared to large-diameter subtypes (Figures S3A and S3C). In addition, most synaptic exocytosis machinery genes display elevated expression in either small-diameter or large-diameter neuron subtype clusters (Figure S3B). On the other hand, expression differences between small-diameter neuron subtypes or between medium and large-diameter neuron subtypes are less dramatic, although many notable differences exist (Figure 3; also see Figures 2C and S2A). These data also revealed many TFs, CAMs, receptors, and ion channels that are uniquely enriched in each of the three small-diameter neuron subtypes, A $\delta$ -LTMRs, and proprioceptors; however, fewer genes in these families distinguish the three A $\beta$ -LTMR subtypes, which likely contributed to the difficulty resolving A $\beta$ -LTMR subtypes in prior single-cell analyses.

### Expression Patterns of Ion Channel Genes in DRG Neuron Subtypes

Our transcriptome profile data resolve patterns and levels of expression of the genes encoding the principal or  $\alpha$  subunits and auxiliary subunits of voltage-gated ion channels expressed in the DRG. This information provides a valuable guide for revealing the molecular identity of the ion channels that underlie subtype-specific intrinsic membrane properties and firing patterns, defined in experiments shown in Figure 1. Therefore, we focused on the patterns of expression of voltage-gated ion channels for each major DRG neuron subtype.

Nav channel  $\alpha$  subunit genes show a clear distinction among the neuronal subtypes (Figure 4A). The most highly expressed Nav channels are Nav1.1, Nav1.6, Nav1.7, Nav1.8, and Nav1.9. Nav1.7 is expressed across all subtypes, with the notable exception of proprioceptors. On the other hand, Nav1.8 and Nav1.9 are most highly expressed in small-diameter neuron subtypes, whereas Nav1.1 and Nav1.6 are abundant in A $\delta$ -LTMRs, the three A $\beta$ -LTMR subtypes, and proprioceptors but very low or undetectable in the small-diameter neuron types.

K channel genes exhibit the greatest diversity among voltage-gated ion channels, with over ninety K channel subunit genes in the mouse genome (Coetzee et al., 1999; Vacher et al., 2008), and many show remarkably different patterns of expression among the DRG neuron subtypes (Figures 4B–4L, S4A–S4D, and S3D). The expression of many different types of K channels is consistent with previous recordings showing multiple components of K current in DRG neurons, with considerable heterogeneity among neurons of different sizes (Everill et al., 1998; Gold et al., 1996). Within the Kv1 subfamily, Kv1.1 expression is elevated in large-diameter neuron subtypes compared to small-

diameter neuron subtypes (Figure 4B). The pattern of Kv1.1 expression was confirmed by immunostaining experiments: most Kv1.1 $^{+}$  neurons are NF200 $^{+}$ , but they do not express MrgD or TH, markers of MrgD $^{+}$  nonpeptidergic nociceptors and C-LTMRs, respectively (Figures S5C and S5D). Kv1.2 expression is also relatively high in the large-diameter neuronal subtypes, especially compared to MrgD $^{+}$  nonpeptidergic nociceptors, and, as with Kv1.1, this finding was supported by immunostaining: most Kv1.2 $^{+}$  neurons are NF200 $^{+}$ , and Kv1.2 $^{+}$  neurons do not express MrgD (Figure S5E). Kv1.6 expression, on the other hand, is elevated in the small-diameter neuron subtypes and low or undetectable in large-diameter neuron subtypes. At least one Kv2 channel family member is expressed relatively abundantly (reads per kilobase per million reads [rpkm]  $\geq$  15) in each of the neuronal subtypes (Figure 4C). Of the Kv3 channel family members, Kv3.1 and Kv3.3 are both enriched in the large-diameter neuron subtypes (Figure 4D); Kv3.1 is particularly highly enriched in proprioceptors, where it may be critical for their fast spiking property. Both peptidergic and non-peptidergic nociceptors express Kv3.4 channels, consistent with recent electrophysiology, single-cell qPCR, and immunocytochemistry (Muqeem et al., 2018; Ritter et al., 2012, 2015). Of the Kv4 family, Kv4.1 was expressed in all eight subtypes, consistent with widespread expression in DRGs seen by immunocytochemistry (Matsuyoshi et al., 2012; Phuket and Covarrubias, 2009), and Kv4.3 is uniquely and highly expressed in C-LTMRs (Figure 4E); this pattern was verified by immunostaining using Kv4.3-specific antibodies (Figure S5F). These results identify C-LTMRs as the population of small-diameter DRG neurons previously associated with high Kv4.3 expression (Phuket and Covarrubias, 2009).

Among other differentially expressed K channel  $\alpha$  and auxiliary subunit genes, BK and SK1 channels are elevated in MrgD $^{+}$  non-peptidergic nociceptors (consistent with previous work showing enrichment of BK current in a subpopulation of nociceptors; Zhang et al., 2010), and Kv7.4 expression is elevated in A $\delta$ -LTMRs, A $\beta$  RA-LTMRs, and A $\beta$  field-LTMRs (Figures 4G and 4L). The latter observation is consistent with the finding that Kv7.4 protein is detected in lanceolate endings and circumferential endings, but not in Merkel-cell-associated endings (Heidenreich et al., 2011). The highly diverse patterns of expression of Kv5, Kv6, Kv8, and Kv9 family members (Figures 4F, 4H, and 4I) suggests that the complexity of K channel compositions among the DRG neuron subtypes is further increased by distinct heteromers formed between these electrically silent (modulatory) channel subunits and Kv2 channels (Bocksteins and Snyders, 2012).

Other voltage-gated ion channel genes, including Cav channels and HCN family members, are also differentially expressed among the eight major DRG neuron subtypes (Figures S4E–S4I). Cav2.1 (P-type) and Cav2.2 (N-type) calcium channels are

### Figure 3. Functionally Relevant Genes Are Differentially Expressed across DRG Sensory Neuron Subtypes

(A–D) Heatmaps depicting expression patterns for genes encoding transcription factors and transcriptional regulators (A), cell adhesion molecules (B), G-protein-coupled receptors (C), and ion channels (D). Plotting scheme, calculation for average expression and calculation for expression deviation from average are the same as in Figure 2D. Only genes that are both highly expressed (average expression in the upper 75<sup>th</sup> percentile) and highly variable (at least three samples have an expression deviation from average larger than 1) were included in the heatmaps.

See STAR Methods for details.

 (A–L) Bar plots depicting expression patterns of genes encoding Nav channel  $\alpha$  and  $\beta$  subunits (A), Kv1 subunits (B), Kv2 subunits (C), Kv3 subunits (D), Kv4 subunits (E), Kv5 and Kv6 subunits (F), Kv7 subunits (G), Kv8 subunits (H), Kv10 subunits (I), inward-rectifier potassium channel subunits (K<sub>ir</sub>; IRK) (K), and calcium-activated potassium channel  $\alpha$  subunits (L). Data are reported as mean  $\pm$  SD.

**Figure 5. Kv Channel Families Differentially Contribute to Outward Current in Sensory Neuron Subtypes**

(A) Heatmap depicting expression patterns of the most abundantly expressed Kv1, Kv2, Kv3, and Kv4 subunits. Plotting scheme is as Figure 2D.

(B–E) Components of Kv current during the AP of A $\beta$  SA1-LTMRs (B), A $\beta$  RA-LTMRs (C), MrgD $^+$  nonpeptidergic nociceptors (D), and C-LTMRs (E). Current was evoked by AP waveforms (previously recorded in a different cell of each type), and components of current were isolated by sequential cumulative application of 100 nM  $\alpha$ -dendrotoxin (DTX), 100  $\mu$ M 4-aminopyridine (4-AP), 3  $\mu$ M AmmTx3, and 100 nM Guangxitoxin-1E (GxTX) to identify Kv1, Kv3, Kv4, and Kv2 currents, respectively.

(B'–E') Currents evoked by a step depolarization to +20 mV (30 ms), applied in parallel with the AP commands in the same cells as (B)–(E).

(F) Stacked bar plots showing the average fraction of total outward K $^+$  current carried by Kv1, Kv2, Kv3, and Kv4 channels in A $\beta$  SA1-LTMRs (AP waveform: 31%  $\pm$  3% Kv1, 0%  $\pm$  1% Kv2, 59%  $\pm$  3% Kv3, 7%  $\pm$  1% Kv4; step to +20 mV: 9%  $\pm$  2% Kv1, 35%  $\pm$  3% Kv2, 22%  $\pm$  3% Kv3, 1%  $\pm$  1% Kv4; n = 15), A $\beta$  RA-LTMRs (AP waveform: 33%  $\pm$  4% Kv1, 0%  $\pm$  2% Kv2, 58%  $\pm$  4% Kv3, 8%  $\pm$  2% Kv4; step to +20 mV: 6%  $\pm$  3% Kv1, 45%  $\pm$  8% Kv2, 16%  $\pm$  7% Kv3, 6%  $\pm$  3% Kv4; n = 11),

(legend continued on next page)

relatively highly expressed in all subtypes, with much lower expression of Cav1.2 L-type calcium channels and very low expression of Cav1.3 channels. For T-type calcium channels, the expression of Cav3.2 is elevated in C-LTMRs and A $\delta$ -LTMRs (Figure S4E), consistent with previous studies (Fran $\ddot{\text{e}}$ ois et al., 2015; Wang and Lewin, 2011). Thus, each DRG neuronal subtype exhibits a unique combination of voltage-gated ion channels that together shape transduction of sensory information.

### Major K Channel Families Differentially Contribute to Outward Potassium Currents in a Subtype-Specific Manner

The unique combinations of Kv channel expression patterns among DRG sensory neuron subtypes suggests that differential expression of these particular ion channels is a key determinant of subtype-specific intrinsic physiological properties. The expression patterns of Kv1–Kv4 channels (Figures 5A and 4A–4D) suggest that Kv1, Kv2, and Kv3, but not Kv4.3, may mediate large outward potassium currents in A $\delta$ -LTMR and A $\beta$ -LTMR subtypes. Another prediction is that Kv4.3, but not Kv3 or Kv1, carries large outward potassium current in C-LTMRs. To test these and other possibilities raised by the sequencing analysis, we quantified the contributions of Kv1, Kv2, Kv3, and Kv4 channels to total potassium current in the genetically defined subtypes using pharmacological dissection of the current.

We quantified the fraction of each current involved in repolarizing the AP in each cell type by using previously recorded AP waveforms in each DRG neuron subtype (Figure 1) as a voltage command and then cumulatively applying a series of Kv1, Kv2, Kv3, and Kv4 inhibitors in an order designed to maximize selective inhibition at each step (Figures S5A, S5A', and S5B). Total K current was defined at the end of the sequence using a high concentration (158.5 mM) of Tetraethylammonium (TEA) together with all the Kv channel inhibitors.

Using this protocol, we found that, in A $\beta$  SA1-LTMRs and A $\beta$  RA-LTMRs, Kv1 and Kv3 account for >80% of total potassium current during their APs (Figures 5B, 5C, and 5G). These two Kv channel families also account for the majority of potassium current during the AP in proprioceptors (19%  $\pm$  5% from Kv1 and 40%  $\pm$  6% from Kv3; n = 11). We compared the currents activated during the AP waveform with that activated by a step to +20 mV for 30 ms, long enough to achieve maximal activation for each channel type. Interestingly, in A $\beta$  SA1-LTMRs and A $\beta$  RA-LTMRs, Kv2 channels underlie a major component (~60%–70%) of potassium current during 30-ms step depolarizations to +20 mV but contribute almost no current during the AP (Figures 5B', 5C', and 5G), apparently because of the slow opening kinetics of Kv2 channels and the relatively narrow AP waveforms of A $\beta$ -LTMR subtypes. On the other hand, in MrgD $^+$  nonpeptidergic nociceptors, which have wide AP waveforms, Kv2 channels contribute substantial current during both AP and step depolarization commands, along with Kv1 and Kv4 channels; Kv3 channels also carry significant current during the AP (13% of the total; Figures 5D, 5D', and

5G). Strikingly, in C-LTMRs, Kv4 channels are the primary mediator (>80%) of potassium current during both step depolarization and the AP (Figures 5E, 5E', and 5G), thus revealing a major difference compared to A $\beta$ -LTMRs, where Kv4-mediated current is minor. Thus, overall potassium current is comprised of considerably different combinations of current from the various Kv channel families in the different DRG neuron subtypes.

### Kv1 Channels Govern Firing Patterns in a Subtype-Specific Manner

We next explored the functional roles of key differentially expressed Kv channels in shaping subtype-specific firing properties. We explored the effect of inhibiting Kv1 channels using the Kv1 blocker  $\alpha$ -DTX. All the cell types expressed various Kv1 subunits, primarily Kv1.1, Kv1.2, and Kv1.6, with differing expression levels in the different cell types of each subunit, all of which are targeted by  $\alpha$ -DTX. In A $\beta$  SA1-LTMRs and A $\beta$  field-LTMRs, which both express high levels of Kv1.1 and Kv1.2, blocking Kv1 channels with  $\alpha$ -DTX dramatically converted their characteristic strongly adapting firing patterns to sustained repetitive firing lasting throughout a 500-ms current injection (Figures 6A–6D). In A $\beta$  RA-LTMRs, which express substantial Kv1.1 and Kv1.2 subunits (but less than A $\beta$  SA1-LTMRs),  $\alpha$ -DTX enhanced firing for small depolarizations but had little effect on repetitive firing evoked by large current injections (Figures 6E and 6F). In both MrgD $^+$  nonpeptidergic nociceptors and C-LTMRs, Kv1.6 is enriched compared to medium and large-diameter neuron subtypes. These two subtypes of small-diameter neurons both responded to  $\alpha$ -DTX application but in different ways, with  $\alpha$ -DTX substantially increasing the maximal firing rate of MrgD $^+$  nonpeptidergic nociceptors, which is relatively low (~10 Hz) in control conditions (Figures S6A and S6B), while having little effect on maximal firing rate of C-LTMRs (which in control conditions fire up to ~28 Hz) but inducing an early cessation of firing and thus a rapid drop in spike number during large-current injections (Figures S6C and S6D). This effect may result from a more depolarized membrane potential during the trough between APs, facilitating inactivation of sodium channels. These findings show that inhibiting Kv1 currents alters firing of most DRG subtypes, in line with previous reports on both large-diameter (Glazebrook et al., 2002) and small-diameter (Chi and Nicol, 2007) primary sensory neurons but with a wide range of effects on firing in different cell types. The differing effects likely reflect a combination of the levels of expression together with the different context of all the other channel types in the neurons as well as potentially different kinetic properties of Kv1 channel subunit compositions (including accessory subunits).

### Kv4.3 Uniquely Regulates the Delayed Firing Pattern of C-LTMRs

In contrast to A $\beta$ -LTMRs, Kv4 channels are the major source of K current in C-LTMRs. In addition, *in vivo* immunostaining showed

MrgD $^+$  nonpeptidergic nociceptors (AP waveform: 20%  $\pm$  4% Kv1, 29%  $\pm$  6% Kv2, 13%  $\pm$  3% Kv3, 37%  $\pm$  6% Kv4; step to +20 mV: 11%  $\pm$  3% Kv1, 34%  $\pm$  7% Kv2, 4%  $\pm$  2% Kv3, 27%  $\pm$  4% Kv4; n = 11), and C-LTMRs (AP waveform: 7%  $\pm$  2% Kv1, 10%  $\pm$  1% Kv2, 0%  $\pm$  3% Kv3, 86%  $\pm$  3% Kv4; step to +20 mV: 4%  $\pm$  2% Kv1, 19%  $\pm$  2% Kv2, 10%  $\pm$  2% Kv3, 67%  $\pm$  3% Kv4; n = 11; mean  $\pm$  SEM). Current contributions were quantified by integrating the currents during the AP or the 30-ms step depolarization.

(B, D, and F) Number of spikes during 500-ms current injections are plotted against injected current density before (black curve) and after (red curve)  $\alpha$ -DTX for A<sub>β</sub> SA1-LTMRs (B; n = 6), A<sub>β</sub> field-LTMRs (D; n = 13), and A<sub>β</sub> RA-LTMRs (F; n = 15). Data are represented as mean  $\pm$  SEM.

that Kv4.3 is present on peripheral endings and likely at central terminals of C-LTMRs, suggesting a unique function of Kv4.3 in these neurons (Figure S7). Therefore, we next recorded C-LTMR firing patterns in the presence and absence of the Kv4 channel blocker AmmTx3. Interestingly, AmmTx3 application greatly reduced the long latency to the first AP following current injection, normally a distinguishing feature of C-LTMRs (Figures 7A and 7C). Complementary experiments were per-

formed using mice in which the *Kcnd3* (Kv4.3) gene was ablated (Figures 7B and 7C). Consistent with the pharmacology experiments, C-LTMRs with a targeted deletion of Kv4.3 exhibited a markedly reduced latency to the first AP, confirming that Kv4.3 is indeed essential for the delayed firing of C-LTMRs. Thus, as with Kv1 family members and A<sub>β</sub>-LTMR subtypes, Kv4.3 is uniquely expressed in C-LTMRs and governs unique aspects of their intrinsic physiological properties.

### Computational Modeling Defines Roles of Kv1 and Kv4.3 Channels

These pharmacological and genetic manipulation experiments support the notion that expression of unique combinations of voltage-gated ion channels in the eight DRG sensory neuron subtypes (summarized in Figure 7D) are critical for subtype-specific intrinsic physiological properties. To further explore how expression levels of key channels control neuronal firing properties, we constructed computational models incorporating the major subtypes of Nav and Kv channels expressed in the sensory neuron subtypes (Figure 8). Setting the size of each

conductance guided by the relative levels of RNA and the maximal conductances defined by voltage steps resulted in AP shapes and firing patterns similar to experimental recordings (Figures 8A–8D and 8A'–8D'). The models recapitulated the essential role of Kv1 channels in producing non-repetitive firing in A $\beta$  SA1-LTMRs (Figures 8D–8F) and the key role of Kv4 channels in controlling the long-onset latency of firing in C-LTMRs seen experimentally (Figures 8D'–8F'). The model showed that the effect of Kv4 to produce delayed firing, also noted in some central neurons (Molineux et al., 2005; Shibata et al., 2000), occurs because Kv4 current activates rapidly at subthreshold voltages but then inactivates over  $\sim$ 100 ms, producing a slow approach to threshold. This mechanism is particularly effective in C-LTMRs because spike threshold is relatively depolarized ( $\sim$ –25 mV) compared to A $\beta$  neurons ( $\sim$ –50 mV) as a result of lack of low-threshold Nav1.6 expression and the depolarized activation range of Nav1.8 channels.

We also explored the impact of varying the levels of Kv1 and Kv4 in the A $\beta$  SA1-LTMR and C-LTMR model neurons, respectively (Figures 8G and 8G'). In the A $\beta$  SA1-LTMR model, the range of injected current amplitudes for which the model neuron fired a single spike displayed a near-linear change as  $\bar{g}_{Kv1}$  was varied between 1 and 5 mS/cm $^2$ . This suggests that differences in Kv1 levels observed between A $\beta$  SA1-LTMRs and A $\beta$  RA-LTMRs in the RNA sequencing (RNA-seq) data and also in voltage-clamp recordings may explain the respective non-repetitive-firing and repetitive firing patterns of these two LTMR subtypes in the experimental recordings. For the C-LTMR

(D and E) Firing patterns of A $\beta$  SA1-LTMR model neuron evoked by 500-ms sustained current injections with Kv1 ( $\bar{g}_{Kv1} = 6 \text{ mS/cm}^2$ ; D) or with Kv1 removed from the model (E).

(legend continued on next page)

computational model, increasing  $\bar{g}_{Kv4}$  increased the AP onset latency at all levels of current injection, as larger Kv4 current required more complete inactivation for spike threshold to be reached.

## DISCUSSION

Although it is well established that primary somatosensory neurons of the DRG are tuned to distinct stimuli and display unique firing patterns, the molecular machinery underlying their unique properties has remained largely elusive. Here, we used a combination of sensory neuron subtype-specific genetic labeling and deep RNA sequencing to generate transcriptome profiles for each of eight major DRG neuron subtypes. The deep transcriptome analysis dataset has unique value for assessing the contributions of genes in a sensory neuron subtype-specific manner. Although prior bulk sequencing or microarray studies using genetically labeled DRG neuron subtypes have been reported, these studies either used genetic tools targeting broad populations of DRG neurons rather than functionally or physiologically defined subsets or sequenced a limited number of subtypes (Chiu et al., 2014; Fleming and Luo, 2013). In addition, although previous unsupervised single-cell RNA sequencing (scRNA-seq) studies of DRG neurons have provided valuable resources (Li et al., 2016; Usoskin et al., 2015), these prior studies did not resolve several key functionally distinct neuronal subtypes, notably the A $\beta$ -LTMR subtypes. This is likely due to the relatively small numbers of A $\beta$ -LTMRs, similarities in their gene expression patterns, especially for A $\beta$  SA1-LTMRs and A $\beta$  field-LTMRs, the small numbers of neurons sequenced in prior studies, and the potential difficulty maintaining the integrity of large-diameter DRG neurons during isolation procedures. For guiding functional analyses, the transcriptome profiles generated in the present study cover eight major DRG neuron subtypes, including three A $\beta$ -LTMR subtypes, A $\delta$ -LTMRs, and C-LTMRs, with high sequencing depth. Indeed, the transcriptome profiles reported here reveal a large number of functionally relevant genes, including voltage-gated Na<sup>+</sup>, K<sup>+</sup>, and Ca<sup>2+</sup> channels, and many lowly expressed genes that are differentially expressed across DRG neuron subtypes, thus providing a resource for identifying molecular underpinnings of subtype-specific electrophysiological properties and functions. The transcriptome profiles also reveal genes useful for generating new genetic tools, as demonstrated here for Calb1 (Figures S2C–S2J). Thus, the present deep sequencing analysis of genetically defined DRG sensory neuron subtypes complements and extends previous RNA-seq studies. A notable disadvantage of our present bulk sequencing strategy is that we could not identify new neuronal subtypes within the broad CGRP<sup>+</sup> peptidergic nociceptor population,

which we found to be physiologically heterogeneous. Moreover, our genetic labeling strategies did not account for ~15% of DRG neurons, which likely include several small-diameter nonpeptidergic neuron populations and select subtypes of glabrous skin and deep tissue-innervating LTMRs. Future work using advanced scRNA-seq approaches for larger scale analyses may be useful for defining transcriptional profiles of neuronal subtypes not covered in the present study.

The transcriptome profiles presented here reveal a great diversity of voltage-gated ion channels expressed among the neuronal subtypes. One of the most notable differences observed is for Nav channels, of which the expression patterns are largely consistent with previous work that assessed the distribution of Nav channels in DRG neurons with different sizes (Dib-Hajj et al., 2010). Although a recent study suggested that Nav1.1 uniquely functions in myelinated nociceptors (Osteen et al., 2016), our findings implicate this channel, along with Nav1.6, as the major determinants of Nav currents in most and possibly all large-diameter DRG sensory neuron subtypes. This is particularly interesting when considering approaches to block or reduce excitability of large-diameter sensory neuron types, including A $\beta$ -LTMR subtypes for the prevention of tactile hypersensitivity and mechanical allodynia in neuropathic pain states. Future work will be required to assess the relative contributions of Nav1.1 and Nav1.6 in A $\delta$ -LTMRs, A $\beta$  RA-LTMRs, A $\beta$  SA1-LTMRs, and A $\beta$  field-LTMRs under both normal and disease conditions.

Toward our goal of defining the molecular basis of sensory neuron subtype-specific intrinsic membrane properties, we used the transcriptome findings to guide an analysis of the contributions of several families of Kv channels. The results of both pharmacological block and computational modeling suggest that Kv1.1 and Kv1.2, which are highly expressed in A $\beta$  SA1-LTMRs and A $\beta$  field-LTMRs, are responsible for the strong adaptation of these neurons. C-LTMRs are unusual in that the dominant potassium current is from A-type Kv4 channels, reflecting high expression of Kv4.3 subunits. Genetic deletion, pharmacological inhibition, and computational modeling all showed that Kv4.3-mediated current is critical for the delayed firing property of C-LTMRs, which is a unique electrophysiological signature of these neurons.

Our electrophysiological analysis focused on the firing patterns of DRG cell bodies. Of course, different cell regions almost certainly have different expression levels of the channels described herein (Trimmer, 2015). In future work, it will be important to explore possible region-specific expression of the channels. In the case of Kv4.3 in C-LTMRs, immunohistochemical analysis showed that this channel is distributed throughout the entire cell surface of C-LTMRs, including its peripheral lanceolate endings around hair follicles and likely its central terminals in

dorsal horn lamina II<sub>IV</sub>. This subcellular localization pattern is in contrast to brain neurons, in which Kv4.3 is highly polarized, with localization limited to dendrites, and in certain cells to cell bodies, but not on axons in any cell types investigated (Trimmer, 2015; Vacher et al., 2008). Considering that Kv4.3 operates within the subthreshold voltage range, this channel may function in the cutaneous ending to mediate signal integration and govern AP initiation, which in turn may explain the observation that C-LTMRs are most highly sensitive to stroking across the skin at low speeds (Bessou et al., 1971; Löken et al., 2009).

In summary, deep sequencing of genetically labeled sensory neuron subtypes has afforded an opportunity to explore the molecular determinants of DRG sensory neuron subtype-specific intrinsic physiological properties. Our pharmacological and genetic dissection of a subset of K channels as well as computational modeling reveal unique roles of channel families in shaping firing properties. These analyses demonstrate the predictive value of the transcriptome data for revealing ion channels of somatosensory neuron subtype-specific intrinsic firing properties. The transcriptome profiles may also guide analyses of functions of other genes in somatosensation.

## STAR METHODS

Detailed methods are provided in the online version of this paper and include the following:

- KEY RESOURCES TABLE
- LEAD CONTACT AND MATERIALS AVAILABILITY
- EXPERIMENTAL MODEL AND SUBJECT DETAILS
  - Mice
- METHOD DETAILS
  - Tamoxifen treatment
  - Current- and voltage-clamp experiments
  - Recordings
  - *In vitro* mechanoclamp experiments
  - Fluorescence-activated cell sorting (FACS)
  - RNA sequencing
  - Trimethoprim treatment and characterization of *Calb1*<sup>dgCre</sup> mice
  - Immunohistochemistry of cryosections
  - Double fluorescent *in situ* hybridization (FISH) of cryosections
- QUANTIFICATION AND STATISTICAL ANALYSIS
  - *In vitro* electrophysiology analysis
  - *In vitro* mechanoclamp
  - RNA sequencing
  - Computational Modeling
- DATA AND CODE AVAILABILITY

**STAR★METHODS****KEY RESOURCES TABLE**

REAGENT or RESOURCE	SOURCE	IDENTIFIER
<b>Antibodies</b>		
Rabbit anti-GFP (1:1000, IHC)	Invitrogen	Cat# A11122; RRID: AB_221569
Chicken anti-GFP (1:1000, IHC)	Aves	Cat# GFP1020; RRID: AB_10000240
Rabbit anti-dsRed (1:1000, IHC)	Clontech	Cat# 632496; RRID: AB_10013483
Goat anti-mCherry (1:500, IHC, WM)	Sicgen	Cat# Ab0040-200; RRID: AB_2333092
Rabbit anti-NF200 (1:1000, IHC)	Sigma	Cat# N4142; RRID: AB_477272
Chicken anti-NFH (1:1000, IHC)	Aves	Cat# NFH0211; RRID: AB_2313552
Rabbit anti-TrpC3 (1:300, IHC)	Alomone Labs	Cat# ACC-016; RRID: AB_2040236
Rabbit anti-GABA(A) $\alpha 1$ receptor (1:300, IHC)	Alomone Labs	Cat# AGA-001; RRID: AB_2039862
Rabbit anti-GABA(A) $\alpha 3$ receptor (1:300, IHC)	Alomone Labs	Cat# AGA-003; RRID: AB_2039866
Rabbit anti-Calbindin (1:500, IHC)	Swant	Cat# CB-38; RRID: AB_10000340
Goat anti-TrkB (1:500, IHC)	R&D Systems	Cat# AF1404; RRID: AB_2155412
Goat anti-TrkB (1:500, IHC)	R&D Systems	Cat# AF1494; RRID: AB_2155264
Rabbit anti-CGRP (1:1000, IHC)	Immunostar	Cat# 24112; RRID: AB_572217
Rabbit anti-TH (1:1000, IHC)	Millipore	Cat# AB152; RRID: AB_390204
Sheep anti-TH (1:500, IHC)	Millipore	Cat# AB1542; RRID: AB_90755
Rabbit anti-S100 (1:500, WM)	Dako	Cat# Z031129-2; RRID: AB_2315306

**LEAD CONTACT AND MATERIALS AVAILABILITY**

Further information and requests for resources and reagents should be directed to and will be fulfilled by the Lead Contact David Ginty ([david\\_ginty@hms.harvard.edu](mailto:david_ginty@hms.harvard.edu)).

**EXPERIMENTAL MODEL AND SUBJECT DETAILS****Mice**

All mouse lines are listed in the [Key Resources Table](#). Mice were group housed in a climate-controlled environment with *ad libitum* access of food and water, on a 12-hour light/dark cycle (7AM lights on and 7PM lights off). Mice were handled and housed in accordance with the Harvard Medical School and Johns Hopkins University IACUC guidelines. For all analyses, the morning after coitus (vaginal plug is seen) was designated as embryonic day 0.5 (E0.5) and the day of birth as postnatal day 0 (P0). Mice were ear tagged before postnatal day 21 or toe tagged at postnatal day 5-7 for determination of their genotypes. Chemical administration protocols for certain mouse lines are described in the [Method Details](#) section. For all experiments, both male and female adult mice (over postnatal day 21 old) on a mixed background were used.

**METHOD DETAILS****Tamoxifen treatment**

Tamoxifen was dissolved in ethanol (20 mg/ml), which was stored at -20°C, then mixed with double volume of sun flower seed oil (Sigma), vortexed for 5-10 minutes and centrifuged under vacuum for 20-30 min to remove the ethanol. The working solution (10 mg/ml) was kept at -20°C and delivered via oral gavage. For labeling C-LTMRs, 2 mg/day for two days of tamoxifen were given at either P13-14 or P21-22. The latter was used for *Th*<sup>2A-CreER</sup>; *R26*<sup>sls-tdTomato</sup>; *Kcnd3*<sup>-/-</sup> mice after weaning, so that parents avoided exposure to tamoxifen. Labeling specificity at both time windows is high. For labeling A $\delta$ -LTMRs, tamoxifen was given to *TrkB*<sup>CreER</sup>; *R26*<sup>sls-tdTomato</sup> (*A14*) mice at E12.5-14.5 to reduce glial cell labeling, which was critical for FACS sorting. For labeling A $\beta$  SA1-LTMRs, tamoxifen was given to *TrkC*<sup>CreER</sup>; *Ret*<sup>fGFP</sup> at E12.5 before 1PM; tamoxifen delivery at a later time point may increase off-target labeling.

**Current- and voltage-clamp experiments****Preparation of DRG neurons**

Acutely dissociated DRG neurons were prepared using enzymatic treatment as previously described ([Liu et al., 2017](#)). Briefly, DRG neurons were removed from mice (over P21), cut in half and treated for 20 minutes at 37°C with 20 U/ml papain (Worthington Biochemical, Lakewood, NJ) and 5 mM DL-cysteine in a calcium- and magnesium-free (CMF) Hank's buffer containing 137 mM NaCl, 5.36 mM KCl, 0.33 mM Na<sub>2</sub>HP4, 0.44 mM KH<sub>2</sub>PO<sub>4</sub>, 5 mM HEPES, 5.55 mM glucose, 0.001% phenol red, pH 7.40 adjusted

with NaOH; 300~310 mOsm. Ganglia were then treated for 20 minutes at 37°C with 3 mg/ml collagenase (type I; Roche Diagnostics, Indianapolis, IN) and 4 mg/ml dispase II (Roche Diagnostics) in CMF Hank's buffer. Cells were dispersed by trituration with a fire-polished glass Pasteur pipette in a solution composed of two media combined in a 1:1 ratio: Leibovitz's L-15 medium (Invitrogen, Grand Island, NY) supplemented with 5 mM HEPES, and DMEM/F12 medium (Invitrogen); this solution also had added 100 ng/ml nerve growth factor (NGF) (Invitrogen). Cells were then plated on glass coverslips treated with 40 µg/ml poly-D-lysine and then 20 µg/ml laminin (Invitrogen). Then cells were incubated at 37°C (95% O<sub>2</sub>, 5% CO<sub>2</sub>) for 3 hours, after which Neurobasal medium (Invitrogen) containing B-27 supplement (Invitrogen), penicillin and streptomycin (Sigma, St. Louis, MO), and 100 ng/ml NGF was added to the Petri dish. Cells were stored at 4°C and used within 48 hours. DRG neurons with specific molecular markers were chosen for following electrophysiological recordings.

### **Recordings**

Recordings were performed at 37°C using an Axon Instruments Multiclamp 700B Amplifier (Molecular Devices). Voltage or current commands were delivered and signals were recorded using a Digidata 1321A data acquisition system (Molecular Devices) controlled by pCLAMP 9.2 software (Molecular Devices). Electrodes were pulled on a Sutter P-97 puller (Sutter Instruments) and shanks were wrapped with Parafilm (American National Can Company) to allow optimal series resistance compensation without oscillation. The resistances of the pipettes were 2-4 MΩ. Seals were formed in Tyrode's solution consisting of 155 mM NaCl, 3.5 mM KCl, 1.5 mM CaCl<sub>2</sub>, 1 mM MgCl<sub>2</sub>, 10 mM HEPES, 10 mM glucose, pH 7.4 adjusted with NaOH. After establishing whole-cell recording, cell capacitance was nulled and series resistance was partially (70%–85%) compensated. The cell was then lifted and placed in front of a series of quartz fiber flow pipes attached with cyanoacrylate glue to a rectangular aluminum rod (cross section 1.5 cm × 0.5 cm) whose temperature was controlled to 38°C using resistive heating elements and a feedback-controlled temperature controller (TC-344B, Warner Instruments). The end of the rod as well as the flow pipes (extending 1 mm from the end of the rod) were lowered just to the surface of the bulk chamber solution, which was locally quickly warmed by the rod; with the temperature of the aluminum rod set to 38°C, the solution exiting from the flow pipes was measured at 37°C (Carter and Bean, 2009). All flow pipes are heated identically and continuously, allowing rapid solution changes without fluctuations of temperature. Solutions were changed (in ~1 s) by moving the cell from one pipe to another.

### **Solutions**

The standard recording solutions had quasi-physiological ionic composition, with an internal solution consisting of 140 mM K aspartate, 13.5 mM NaCl, 1.6 mM MgCl<sub>2</sub>, 0.09 mM EGTA, 9 mM HEPES, 14 mM creatine phosphate (Tris salt), 4 mM MgATP, 0.3 mM Tris-GTP, pH 7.2 adjusted with KOH and an external Tyrode's solution consisting of 155 mM NaCl, 3.5 mM KCl, 1.5 mM CaCl<sub>2</sub>, 1 mM MgCl<sub>2</sub>, 10 mM HEPES, 10 mM glucose, pH 7.4 adjusted with NaOH.

### **Sequence of inhibitors for dissecting K current components**

The inhibitors were applied cumulatively in a sequence designed to maximize the effective selectivity for identifying each component of K current by applying imperfectly-selective inhibitors after the main off-target channels had already been inhibited. The K channel inhibitors were applied on a background of TTX (1 µM) and A-803467 (1 µM) to inhibit Na channels. First, α-dendrotoxin (Alomone Labs), which is highly selective for Kv1.1, Kv1.2, and Kv1.6 channels (Harvey and Robertson, 2004), was applied at 100 nM. Next, 4-aminopyridine (4-AP) (Sigma) was applied at 100 µM, a concentration which should inhibit Kv3 channels almost completely while having minimal effects on other channels except Kv1, which was already blocked (Coetzee et al., 1999; Gutman et al., 2005). Next the Kv4 inhibitor AmmTx3 (Smartox Biotechnology) (Maffie et al., 2013; Pathak et al., 2016) was applied at 3 µM, followed by the Kv2 inhibitor Guangxitoxin-1E (Peptide Institute) at 100 nM (Liu and Bean, 2014). Finally, a high concentration of TEA was applied (in the continuing presence of the other inhibitors) to inhibit any remaining K current, using a solution in which TEA replaced both Na and K (158.5 mM TEACl, 1.5 mM CaCl<sub>2</sub>, 1 mM MgCl<sub>2</sub>, 10 mM HEPES, 10 mM glucose, pH 7.4 adjusted with TEAOH); block by this solution relative to control was considered to comprise the total K current.

### **In vitro mechanoclamp experiments**

#### **Cell culture**

Digestion solution, which contained 5mg/mL dispase (GIBCO Invitrogen, 17105-041), 2mg/mL collagenase (Type I, Worthington, LS004196) and 0.1mg/mL DNase (Sigma, DN25) in HBSS, was aliquoted and stored in -80°C. DH10 solution was made with 1 × Penicillin-Streptomycin (Pen-Strep) (Life Technologies, 15070-063), 10% SCG FBS (Life Technologies, 16000-044, thawed and heat-inactivated in 55°C water bath for 30 minutes, aliquoted and stored in -20°C) in DMEM (high glucose DMEM, Life Technologies, 11965-118), filtered through 0.2 µm filters, and stored in 4°C for up to a month. Poly-D-lysine coated glass bottom Petri dishes (Mat-Tek, P35GC-1.5-10-C) were coated with 200 µL laminin (10 µg/mL) (Life Technologies, 23017-015), incubated at 37°C overnight. The Petri dishes were rinsed with ddH<sub>2</sub>O three times and dried in a sterile fume hood. DRGs were freshly dissected out from mice (over P21) and placed into ice-cold DH10, briefly washed once in 1 × HBSS, then digested in 1mL digestion solution at 37°C for 30-40 minutes under constant rotation, and then centrifuged at 200 g for 5 minutes. The supernatant was removed while the precipitant was carefully resuspended in 1mL DH10. Resuspended cells were gently triturated for 10-15 times using a pipette tip opening diameter no smaller than 0.5 mm, then allowed to recover for 1-2 minutes before the supernatant was collected and plated on glass areas in the dishes. Petri dishes were incubated in 37°C humidified atmosphere (5% CO<sub>2</sub>) for 20 minutes, then ~2 mL pre-warmed DH10 medium

together with 25 ng/mL nerve growth factor (NGF), 25 ng/mL brain-derived neurotrophic factor (BDNF), 25 ng/mL neurotrophin (NT3) and 2 ng/mL glia-derived neurotrophic factor (GDNF) was added. Neurons were kept in the incubator overnight.

#### **Voltage-clamp with controlled mechanical stimulations**

The method for *in vitro* mechanoclamp experiments was modified from that of [Hao and Delmas, 2011](#). Mechanical probes and patch pipettes were fabricated from borosilicate glass tubing (Sutter, BF150-86-10). Pipettes were pulled on a P-97 pipette puller (Sutter) and fire-polished using a microforge (Narishige, MF-830). Mechanical probes were polished to obtain a blunt tip that had a diameter of 3-4  $\mu\text{m}$ . Patch pipettes had a resistance of 2~4 M $\Omega$ . For voltage-clamp recordings, internal solutions contained 125 mM CsCl, 1 mM MgCl<sub>2</sub>, 4.8 mM CaCl<sub>2</sub>, 10 mM HEPES, 10 mM EGTA, 4 mM Mg-ATP and 0.4 mM Na-GTP with pH adjusted with CsOH to 7.4, osmolarity adjusted to 300 mOsm with CsCl. Extracellular solutions contained 132 mM NaCl, 3 mM KCl, 1 mM MgCl<sub>2</sub>, 2.5 mM CaCl<sub>2</sub>, 10 mM HEPES and 10 mM glucose with pH adjusted with NaOH to 7.4, osmolarity adjusted to 300 mOsm with NaCl. For mechanical stimulation, a piezoelectric actuator (P-601.1S, Physik Instrument) was fixed on a micromanipulator and a pipette holder was mounted on the actuator. The mechanical probe was positioned at an angle 45-60° from the horizontal plane. Movement of the mechanical probe was controlled and monitored using the pCLAMP program. A step protocol was used to deliver mechanical stimulations with increasing displacements at 1  $\mu\text{m}$  increments. The probe moved at a speed of 500  $\mu\text{m}/\text{s}$  (measured between 10%-90% distance) and displacement lasted for 500 ms, followed by a 10 s interval before the next stimulation. The zero position was found as follows: first, the probe tip was moved close to the cell under visual guidance; then a protocol with 4,5,6  $\mu\text{m}$  stimulations was run. When the 4- $\mu\text{m}$  stimulation did not yield any membrane deformation while 6- $\mu\text{m}$  movement yielded visible membrane deformation, the zero position was defined as 5- $\mu\text{m}$  movement of the probe.

#### **Fluorescence-activated cell sorting (FACS)**

For preparation, three solutions were made beforehand. Digestion solution and DH10 medium were prepared and stored as described for the cell culture and *in vitro* mechanoclamp procedures. FACS solution included 50 mg/mL bovine serum albumin (BSA) (Sigma, A6003), 1M HEPES (Sigma, H3375), 1 × Pen-Strep, 0.5 mg/mL DNase in L-15 medium (GIBCO, 11415). FACS solution was made fresh for every FACS experiment. For tissue collection, DRGs from all axial levels (except for proprioceptors, for which only non-limb level DRGs were used, because the genetic strategy used for labeling proprioceptors also labels limb level cutaneous LTMRs.) were freshly dissected from mice (3-12 weeks of age) and placed into ice-cold DH10 with roots carefully removed, briefly washed once in 1 × HBSS, then digested in 1mL digestion solution at 37°C under constant rotation. DRGs from up to six mice were collected for each FACS experiment and the total dissection time was kept under three hours. The digestant was centrifuged at 200 g for 5 minutes. The supernatant was removed while the precipitant was carefully resuspended in 1 mL DH10. Resuspended solutions were gently triturated 10-15 times using a pipette tip opening diameter no smaller than 0.5 mm, rested for 1-2 minutes before supernatants were collected to a new tube and then the precipitants underwent the same process of trituration, rest and collection of supernatants for a second time. Collected supernatants were passed through a 100  $\mu\text{m}$  cell strainer (pre-rinsed with DH10) (Fisher, 08-771-19) followed by 2-3 mL DH10, and all solutions were collected and centrifuged at 200-300 g for 5 minutes. Supernatants were removed, and precipitants were gently resuspended in 8 mL DH10, centrifuged again and the pellets were resuspended in 1 mL FACS solution. The samples were immediately transported to a flow-cytometry facility on ice. MoFlo (Johns Hopkins School of Medicine) and Avalon (Harvard Medical School) sorters with 100  $\mu\text{m}$  or 150  $\mu\text{m}$  nozzles were used to sort fluorescent cells under pressure lower than ~20 psi. Sorting criteria were selected monitoring distribution of GFP and tdTomato signals, forward scatter, side scatter and pulse widths. Propidium iodide (PI) staining was sometimes used to exclude dead cells. A small number of sorted cells was collected on a slide or culture medium and examined under fluorescent microscope during sorting for confirmation of fluorescence. Limited by the minimum amount of input RNA needed for sequencing, at least 2000 neurons were collected for each sample, except for one A $\beta$  RA-LTMR sample that has ~1600 neurons. Sorted cells used for RNA extraction were collected in RNALater solution (Life Technologies, AM7022), centrifuged, placed in 4°C overnight and sometimes stored in -80°C for several days. RNA was purified using the Absolutely RNA nanoprep kit (Agilent, 400753).

#### **RNA sequencing**

Purified RNA samples with a concentration of 1-10 ng/ $\mu\text{L}$  for 8-10  $\mu\text{L}$  and RNA integrity number (RIN) above 7 (except for one sample for A $\beta$  SA1-LTMRs that had a RIN ~6) were selected for library preparation and RNA-sequencing at the Johns Hopkins Deep Sequencing & Microarray Core. cDNA libraries were prepared using Nugen Ovation RNA-Seq and then Illumina TruSeq RNA Library Prep Kit. The cDNA libraries were then sequenced using the Illumina HiSeq 2000 platform with 50 bp single-end reads with 2 × multiplexing (two samples were combined and run for each lane).

#### **Trimethoprim treatment and characterization of *Calb1*<sup>dgCre</sup> mice**

Trimethoprim (TMP) (Sigma, T78883) was dissolved in DMSO (50 mg/ml) and prepared fresh for intraperitoneal injection of mice carrying *Calb1*<sup>dgCre</sup>. Mice were treated with two doses of TMP (100  $\mu\text{g}$  per gram of body weight per day at P18,19) and then sacrificed at P21-P28 for tissue harvesting ([Sando et al., 2013](#)). *Calb1*<sup>dgCre</sup>; *R26*<sup>LSL-FSF-tdTomato</sup> or *Calb1*<sup>dgCre</sup>; *R26*<sup>LSL-FSF-tdTomato</sup> mice display low level of baseline recombination. TMP treatment induced ~10-20 fold increase in the number of tdTomato<sup>+</sup> cells in DRGs (data not

shown). Variable baseline Cre activity was observed when using *Brn3a*<sup>CKOAP</sup> (Badea et al., 2012) as the reporter line between different litters (data not shown), and it is recommended that littermate controls always be used as controls to monitor baseline reporter expression or Cre activity.

### Immunohistochemistry of cryosections

Mice (3-6 weeks) were anesthetized with CO<sub>2</sub> and perfused using 5-10 mL PBS followed by 10-20 mL of 4% paraformaldehyde (PFA) in PBS at room temperature (RT). Vertebral columns (including spinal cords and DRG) and skin were dissected from perfused mice. For immunostaining experiments other than those for Kv4.3, neuronal tissues were post-fixed in 4% PFA at 4°C for 2-4 hours, while skin was post-fixed in Zamboni's fixation buffer at 4°C for 48 hours. For Kv4.3 immunostaining, no post-fixation was used for vertebral columns. For co-staining of Kv4.3 and tdTomato (related to Figure S7), the skin was post-fixed in Zamboni's fixation buffer at 4°C for one hour. In general, the tdTomato signal decreased as fixation times shortened, while the staining background increased as fixation times increased. Using one-hour post-fixation, both signals could be observed, although the tdTomato signal was weak. Tissues were then washed 3 × 20 minutes with PBS at RT. Tissues were cryoprotected in 30% sucrose in PBS at 4°C overnight, embedded in OCT and frozen at -20°C, stored at -20°C for short term and -80°C for long term, and sectioned at 20-25 μm using a cryostat. Sections were collected on slides and outlined using an ImmEdge Hydrophobic Barrier Pen. Vertebral column sections were dried at RT for at least 30 minutes or overnight before staining. Skin sections were dried at RT overnight to 48 hours. Slides were washed 3 × 10min with PBS containing 0.1% Triton X-100 (0.1% PBST) and then blocked in 0.1% PBST containing 10% normal goat serum (Vector Labs, S-1000) or normal donkey serum (Jackson Immuno, 005-000-121) for 30 minutes at RT. Slides were incubated with primary antibodies (listed in Key Resources Table) diluted in 0.1% PBST containing 5% serum at 4°C overnight covered with parafilm (Fisher, PM996). The next day, Slides were washed 3x10 minutes with 0.1% PBST, and incubated with secondary antibodies diluted (species-specific Alexa Fluor 488, 546, and 647 conjugated IgGs, Invitrogen) 1:500 in 0.1% PBST containing 5% serum at room temperature for 2 hours, washed again 3 × 10 minutes with 0.1% PBST, and mounted with fluoromount-G (Southern Biotech).

### Double fluorescent *in situ* hybridization (FISH) of cryosections

Digoxygenin (DIG) (DIG RNA labeling mix, Roche, 11277073910)-labeled sense and antisense probes were generated for Lpar3, Adcyap1, Gpx3, Ptgr, Spp1, and Fluorescein (Fluorescein RNA labeling mix, Roche, 11685619910)-labeled sense and antisense probes were generated for tdTomato and GFP. Five probes for each target gene were generated and tested using single-color *in situ* hybridization, and only probes that displayed robust signals were selected for subsequent analyses. For experiments, multiple solutions were prepared beforehand. Diethyl pyrocarbonate (DEPC)-ddH<sub>2</sub>O and DEPC-PBS are ddH<sub>2</sub>O and PBS treated with DEPC (Sigma, D5758) at 1:1000 ratio, mixed at 37°C for at least 1 hour, then autoclaved. Washing buffer was 100 mM Tris-HCl, 150 mM NaCl, 0.05% Tween-20, pH 7.5 at 20°C. Detection buffer was 100 mM Tris-HCl, 100 mM NaCl, 10 mM MgCl<sub>2</sub>, and pH 8.0 at 20°C. All the solutions were made in advance and stored in RT. Hybridization solution contained 50% formamide, 5 × SSC, 0.3 mg/ml yeast tRNA (Sigma, R6750), 100 μg/ml heparin (Sigma, H3393), 1 × Denhardt's (Sigma, D2532), 0.1% Tween 20, 5 mM EDTA in DEPC-ddH<sub>2</sub>O. Hybridization solution was made in advance and stored at -20°C. Vertebral columns were freshly dissected from mice (3-6 weeks) and frozen in OCT, then sectioned at 20-25 μm using a cryostat. Sections from at least one pair of cervical, thoracic, and lumbar DRGs were sectioned and sections were collected on slides and warmed up at RT for 30 minutes. Sections were fixed in 4% PFA, then washed using freshly prepared DEPC in DEPC-PBS (1/1000) for 10 minutes and washed again with DEPC-PBS for 5 minutes. Slides were incubated in 50 μg/ml proteinase K for 1 to 5 minutes, then washed in DEPC-PBS for 5 minutes and rinsed with DEPC-ddH<sub>2</sub>O (ddH<sub>2</sub>O pretreated with DEPC, and autoclaved). Slides were treated with freshly made 0.1 M TEA buffer (triethanolamine and acetic anhydride in DEPC-ddH<sub>2</sub>O) for 10 minutes at RT, then washed with DEPC-PBS for 5 minutes. Slides were then incubated in hybridization buffer and covered with parafilm and incubated at 65°C in a humidified chamber for 30 minutes, then in hybridization buffer with probes (1 DIG- and 1 fluorescein-labeled) diluted at 1:100 ratio at 65°C overnight. On the second day, slides were washed with 0.2 × SSC once for 15 minutes at 65°C, then twice for 30 minutes each at 65°C. Slides were then incubated with 20% normal goat serum in 0.1% PBST for 30 minutes to an hour at RT, then added with AP labeled antibody (anti-DIG-AP, Roche, 11093274910) diluted at 1:1000-1:2000 in 20% normal goat serum in 0.1% PBST and incubated at RT for 2 hours, then washed 3 × 10 minutes in PBS or washing buffer. HNPP/Fast Red TR mix was prepared fresh, diluting 10 μL HNPP and 10 μL Fast Red TR stock solution in 1 mL detection buffer (HNPP fluorescent detection kit, Roche, 11758888001), then filtered with 0.2 μm filter. Slides were then incubated in HNPP/Fast Red TR mix for 30 minutes at RT, and then washed in washing buffer. Next, slides were incubated in HNPP/Fast Red TR mix and washed repetitively for 3 times, then washed in PBS for 5 minutes, blocked with 0.5% blocking solution (blocking reagent (Roche, 11096176001) diluted in PBS) for 1 hour at RT, and then incubated in POD labeled antibody (anti-fluorescein-POD, Roche, 11426346910) (1:250 diluted in blocking solution). Slides were washed in PBS 3 × 10 minutes at RT, then incubated with TSA Plus Solution (TSA diluted in Amplification Plus Buffer at 1:100) (TSA plus fluorescein system, PekinElmer NEL741001KT) for 15-30 minutes at RT, then rinsed again with PBS. Sections were mounted with fluoromount-G before being examined using confocal microscopy.

## QUANTIFICATION AND STATISTICAL ANALYSIS

### *In vitro* electrophysiology analysis

Current and voltage recordings were filtered at 10 kHz and digitized at 200 kHz. Analysis was performed with Igor Pro 6.12 (WaveMetrics, Lake Oswego, OR), using DataAccess (Bruxton Software) to import pClamp data. Reported membrane potentials are corrected for a liquid junction potential of  $-10$  mV between the internal solution and the Tyrode's solution in which current was zeroed before sealing onto the cell, measured using a flowing 3 M KCl reference electrode. In current clamp experiments, resting potential was adjusted to  $-80$  mV using a steady-holding current. In quantifying action potential firing, action potentials were defined by the criteria that peak voltage is above  $-20$  mV and spike height is at least 30 mV.

Voltage-clamp current records were corrected for linear capacitative and leak current by subtracting scaled responses to 5 mV hyperpolarizations delivered from the holding potential. In AP clamp experiments, APs were evoked by current injection (just above threshold for 0.5 ms) in each cell type and then used as the command waveform in voltage clamp experiments with that cell type. To measure total net outward current during the repolarization phase of the AP, the current was integrated from the time that net current under control conditions became net outward (near the peak of the AP) to the time of the trough following the AP, when net current under control conditions shifted from outward to inward.

### *In vitro* mechanoclamp

Recordings were filtered at 10 kHz and digitized at 20 kHz. Series resistance and junction potential were not compensated or corrected. Access resistance was assessed using membrane test with 5mV hyperpolarizations from the holding potential throughout recordings, and cells displaying significant access time constant change were eliminated from further analysis.

Kinetics of mechanosensitive currents were analyzed using pClamp and determined by using nonlinear least-squares regression analysis applied to the decay phase of the currents. Traces were fit by one or two exponential components as follows:  $I(t) = A_1 \cdot e^{-t/\tau_1} + A_2 \cdot e^{-t/\tau_2} + A_0$ . When two component fitting was required, the faster time constant was used in [Figure 1T](#). Only traces with a fitting correlation over 80% were selected for quantification.

### RNA sequencing

Reads were aligned and counted using STAR aligner and Htseq at Harvard Chan Bioinformatics Core. Both read count matrix and normalized data using reads per kilobase per million reads (rpkm) were obtained. Sequencing data quality was assessed by examining the number of mapped reads (average = 73,506,450), genomic mapping rate (average = 0.93), number of genes detected (19,601 genes that have a count number  $\geq 1$ , 12,226 genes that have a count per million (CPM) value  $\geq 1$ , 11,160 genes that have fpkm value  $\geq 1$ ), exonic mapping rate (average = 0.67), and rRNA mapping rate (average =  $1.86 \times 10^{-6}$ ). Count matrix values were transformed using regularized log transformation implemented in DESeq2 R package and rendered homoscedastic ([Love et al., 2014](#)). Correlations between samples were assessed by clustering samples using all rlog transformed count data and multiple ways to calculate distances (Euclidean Distance, Pearson Correlation, Spearman Correlation). Samples of the same neuronal subtypes generally clustered with each other, and two major-group structures were observed regardless of the methods used (data not shown) (related to [Figures 2C](#) and [S2A](#)). This also held true with performing analysis using kmeans clustering with a k value of 8 (data not shown). Differential expression tests were performed for every pair of neuronal subtypes, also using the DESeq2 package. Differentially expressed genes (DEGs) were defined using the criteria of a 2-fold change with a false discovery rate (FDR)  $< 0.01$ . A differential expression test was also performed comparing small-diameter neuron subtypes to medium and large-diameter neuron subtypes. In the text, all genes that were described as differentially expressed comparing small-diameter to medium and large diameter neuron subtypes satisfy the aforementioned criteria. Subtype uniquely enriched genes (SUEGs) were selected for those that are enriched in the subtype in every pair comparison, thus the FDR criteria for SUEGs after correction for multiple comparisons is  $\sim 0.07$  (related to [Figure 2D](#)). Genes whose expression patterns were tested in [Figures 2E–2L](#) were selected from SUEGs, except for Ptgfr, which was found to be enriched in both A $\beta$  SA1-LTMRs and A $\beta$  Field-LTMRs, compared to other subtypes. For the generation of heatmaps shown in [Figures 2D](#), [S2B](#), [3](#), [S3A](#), [S3B](#), and [5A](#), rlog transformed count data was used as expression measurements and as inputs. Genes were first filtered using the criteria of average rlog value across all samples  $> 0$ , which yielded 18,755 genes, and defined as expressed in Results sections related to individual figures. For the 18,755 genes detected, rlog averaged across 26 samples for every gene was calculated as average rlog values to represent average expression levels. Average rlog is 14.28 at 99th percentile, 12.59 at 95th percentile, 11.76 at 90th percentile, 10.14 at 75th percentile, 7.74 at 50th percentile and 3.60 at 25th percentile. For the 18,755 genes, rlog differences from the average rlog values across all samples for each gene were calculated to represent relative expression enrichment or reduction for each sample. A difference of 1 roughly translates to 2-fold change. Rlog differences were then averaged across samples from the same neuronal subtype to represent subtype gene expression differences. Genes were then grouped based on the neuronal subtype their expression is enriched in, and then ordered based on the enrichment in a descending manner. Only genes that had average rlog values within the top 75% (average rlog  $> 3.60$ ) and displayed expression differences over 1 in three samples (the number of replicates for one neuronal subtype) were selected for displaying the expression pattern. Rlog difference from the average rlog value was plotted in the main heatmaps using a scale of  $-2$  to  $2$  represented using blue to red color scale for the heatmaps. Average rlog values were plotted in a second heatmap to the right of the main heatmap. [Figures S3C](#) and [S3D](#) used the same plotting scheme, but without implementing any filters and all genes belonged to the categories were included in the heatmaps.

Genes were ordered alphabetically. In bar plots displaying gene expression using rpkm values, error bars represent mean  $\pm$  SD (related to Figures 4 and S4). In dotplots displaying gene expression using rpkm values, all data points were plotted (related to Figures 2E–2L). The bar plots were plotted using Prism 7, while heatmaps and dotplots were plotted using the ggplot2 package in R. All the n's are as indicated in figure legends and corresponding methods section.

### Computational Modeling

Computational models were implemented using the NEURON simulation environment (Hines and Carnevale, 1997, 2000). Single cylindrical compartment models were constructed with diameter and length = 19.55  $\mu\text{m}$  to model C-LTMRs (total membrane capacitance  $C_m = 12 \text{ pF}$ ), and with diameter and length = 30.90  $\mu\text{m}$  to model A $\beta$  SA1-LTMRs ( $C_m = 30 \text{ pF}$ ). Specific membrane capacitance ( $c_m$ ) was 1  $\mu\text{F}/\text{cm}^2$  and specific resistivity of the internal solution ( $R_i$ ) was 100  $\Omega\cdot\text{cm}$ . For ion channels, the voltage-gated ion channels Nav1.1, Nav1.6, Nav1.7, Nav1.8, Kv1, Kv2, Kv3, Kv4 and leak channels were included. The voltage-dependence and kinetics of current carried by each voltage-dependent channels was described by  $I = \bar{g}m^ph(V - V_{rev})$ , where  $I$  is the current,  $\bar{g}$  is the maximal conductance with all channels open,  $V$  is the membrane voltage, and  $V_{rev}$  is the reversal potential of the channel.  $V_{rev}$  was +55 mV for sodium channels and -88 mV for potassium channels. Gating of channels was described by the Hodgkin-Huxley-style parameters  $m$  (governing activation) and  $h$  (governing inactivation), each varying between 0 and 1 in a voltage- and time-dependent manner, with  $p$  being an exponent varying from 1 to 4 for different channels. The steady-state voltage dependence of  $m$  was described by a Boltzmann function of the form  $m_\infty = 1/(1 + \exp((-(V - V_h))/k))$ , where  $V_h$  is the voltage at which  $m$  is 0.5 and  $k$  is the slope factor describing the steepness of the function. The steady-state voltage-dependence of  $h$  was described by a Boltzmann function with the opposite direction of voltage-dependence,  $h_\infty = 1/(1 + \exp((V - V_h)/k))$ . The kinetics of gating of  $m$  and  $h$  were expressed by defining a time-constant of gating at each voltage, allowing a more flexible definition of kinetics than is possible by separately defining backward and forward rate constants for each gating particle. The voltage-dependence of the  $m$  or  $h$  time-constants was described by a rising Boltzmann function at more negative voltages and a falling Boltzmann at more positive voltages, allowing more accurate description of gating in cases in which time constants measured by activation and deactivation kinetics fail to converge (e.g., Liu and Bean, 2014). The formula for the time-constant at more negative ("left-side") voltages was  $aL + (bL/(1 + \exp((-(V - cL))/dL)))$ , where  $aL$  corresponds to an asymptotic time-constant at strongly negative voltages and  $bL$  to a projected asymptote at positive voltages, with  $cL$  and  $dL$  governing the shape of the voltage-dependence. The formula for the time-constant at more positive ("right-side") voltages was  $aR + (bR/(1 + \exp((V - cR)/dR)))$ , where  $aR$  corresponds to an asymptotic time-constant at strongly positive voltages and  $bR$  to a projected asymptote at more negative voltages, with  $cR$  and  $dR$  governing the shape of the voltage-dependence. Time-constants were defined by the "left-side" formula at voltages more negative than a "break" voltage (denoted by "VBrk" in Table S1) and by the "right-side" formula at voltages positive to the break voltage (cf. Korngreen and Sakmann, 2000). Parameters describing voltage dependence and kinetics were initially derived from previous studies (Nav1.1: (Rhodes et al., 2004); Nav1.6: (Carter and Bean, 2011; Royeck et al., 2008; Schwarz and Eikhof, 1987); Nav1.7: (Blair and Bean, 2002); Nav1.8: (Blair and Bean, 2002); Kv1: (Glazebrook et al., 2002; Guan et al., 2006); Kv2: (Liu and Bean, 2014); Kv3: (Lien and Jonas, 2003; Martina et al., 2007); Kv4: (Jackson and Bean, 2007)). Gating parameters along with current densities were then adjusted to better match the experimental data from DRG recordings at 37°C. The values for the gating parameters for each type of channel are listed in Table S1. The models for firing of A $\beta$  SA1-LTMRs and C-LTMRs used identical parameters for gating of the voltage-dependent channels, with different combinations and magnitudes of each conductance. A $\beta$  SA1-LTMRs contained Nav1.1 (8 mS/cm $^2$ ), Nav1.6 (40 mS/cm $^2$ ), Nav1.7 (5 mS/cm $^2$ ), Kv1 (6 mS/cm $^2$ ), Kv2 (12 mS/cm $^2$ ), Kv3 (4 mS/cm $^2$ ) and Kv4 (0.8 mS/cm $^2$ ) conductances, as well as a non-voltage dependent leak conductance (0.1 mS/cm $^2$ ) with a reversal potential of -80 mV. C-LTMRs contained Nav1.7 (30 mS/cm $^2$ ), Nav1.8 (40 mS/cm $^2$ ), Kv1 (0.06 mS/cm $^2$ ), Kv2 (2 mS/cm $^2$ ), Kv3 (0.05 mS/cm $^2$ ) and Kv4 (11 mS/cm $^2$ ) conductances, and a non-voltage dependent leak conductance (0.02 mS/cm $^2$ ) with a reversal potential of -80 mV. For displaying the firing behavior in Figure 8, the model was implemented in IgorPRO as well as in NEURON. Firing properties were analyzed and heatmaps were constructed using R.

### DATA AND CODE AVAILABILITY

Computational models are available at ModelDB (<https://senselab.med.yale.edu/modeldb/>, Accession No. 256632). RNA-seq data is available on GEO (Accession number GEO: GSE131230).
